

THE TRACE ANOMALY AND THE PARTON MODEL

S. D. Bass

ABSTRACT

The trace anomaly is relevant to the renormalisation of the unpolarised parton distributions. The coefficient which describes the local γ^* (glue) interaction differs at next-to-leading order between the renormalised operator product expansion and parton model descriptions of deep inelastic scattering – independent of the factorisation scheme.

There are two approaches to the theory of deep inelastic scattering (DIS). These are the operator product expansion (OPE) and the QCD improved parton model (PM) [1]. In both approaches we write the transverse and longitudinal structure functions as the sum over the convolution of soft quark and gluonic parton distributions with hard coefficients, viz.

$$F_{[T,L]}(x, Q^2) = \sum_q e_q^2 x(q + \bar{q}) \otimes C_{[T,L]}^q(x, \alpha_s, Q^2) + xg \otimes C_{[T,L]}^g(x, \alpha_s, Q^2) \quad (1)$$

The hard coefficients $C_{[T,L]}^q$ and $C_{[T,L]}^g$ describe the interaction of the hard photon (carrying transverse or longitudinal polarisation) with the quark and gluon partons.

In the parton model we calculate the deep inelastic cross section from a quark or gluon target to some order in perturbation theory and then use the factorisation theorem to absorb the infra-red collinear singularities into the parton distributions — or, equivalently, the hadron wavefunction. The remaining infra-red safe part of the phase space is identified with the hard coefficients. This factorisation is universal to all inclusive, high-energy hadronic interactions.

Having taken care of the collinear singularities we also need to renormalise the parton distributions. Here we use the operator product expansion, which is applied to the total deep inelastic cross section. The operator product expansion defines the target wavefunction in terms of the matrix elements of a tower of renormalised, local operators [1]. These operator matrix elements need to be renormalised consistent with the symmetry constraints of anomaly theory [2,3] — in this case, the trace anomaly [4]. This renormalisation has to be carried out in addition to the renormalisation of the propagators and vertices in QCD. In this paper I explain how the anomaly induces a difference at next-to-leading order between the quark distributions and gluonic coefficients which are obtained via the operator product expansion and the (factorisation only) parton model. This difference is independent of the factorisation

itself in the gluonic coefficient. Finally, these results are compared with the axial anomaly in polarised deep inelastic scattering.

The parton distributions in equ.(1) are defined with respect to the operator product expansion so that their even moments project out the target matrix elements of the renormalised, spin-even, local operators

$$(p_+)^{2n+2} \int_0^1 dx x^{2n+1} \left[q(x, Q^2) + \bar{q}(x, Q^2) \right]_k = \langle p | \left[\bar{q}(0) \gamma_+ (iD_+)^{2n+1} \frac{\lambda_k}{2} q(0) \right]_{Q^2}^R | p \rangle_c \quad (2)$$

and

$$(p_+)^{2n+2} \int_0^1 dx x^{2n+1} g(x, Q^2) = \langle p | \left[\text{Tr} G_{+\alpha}(0) (iD_+)^{2n} G_{+\alpha}^\alpha(0) \right]_{Q^2}^R | p \rangle_c \quad (3)$$

Here $G_{\mu\nu}$ is the gluon field tensor, $D_\mu = \partial_\mu + igA_\mu$ is the gauge covariant derivative in QCD and p_μ is the proton momentum vector. The second ($n = 0$) moment of the quark (gluon) distribution projects out the target matrix element of the quark (gluon) part of the energy-momentum tensor $\theta_{\mu\nu}$ in QCD. The operators in eqs.(2,3) should be quoted with respect to some renormalisation prescription R — here we have written them at the subtraction point $\mu^2 = Q^2$.

The problem of anomalies is related to the symmetry of the Dirac sea at infinite momentum. When we quantise the theory about some background mean field (the non-perturbative vacuum) then we construct the Fock expansion by keeping quark and gluon quanta with momentum less than some ultra-violet cut-off λ . High momentum (short distance) fluctuations greater than this cut-off are absorbed into the theory as part of the definition of the mean field. The anomaly has an analogy in classical physics where we consider a thermodynamic system in equilibrium with a heat bath [5]. There can be a nett flow of energy between the system and the heat bath at equilibrium so that the *bare* energy of the system is not conserved. However, we can write down a *free* energy, which is conserved. We may think of the perturbative Fock space as the system and the mean field as the heat bath. One finds that there is a flux of energy between the mean field and the Fock space but the free energy remains constant [5]. The physical energy momentum tensor $\theta_{\mu\nu}$ corresponds to the free energy. It is conserved but picks up a finite trace due to the anomaly [6]:

$$\theta_\mu^\mu = (1 + \gamma_m) \sum_q m_q \bar{q}q + \frac{\beta(\alpha_s)}{4\alpha_s} G_{\mu\nu} G^{\mu\nu}. \quad (4)$$

Here m_q is the running quark mass, γ_m is the mass anomalous dimension and $\beta(\alpha_s)$ is the QCD beta function. We can regard the Fock space as a closed system (independent of the mean field) only when we consider anomaly free quantities such as the vector current, which measures the valence quark number. The anomalous gluonic term in equ.(4) is particularly important in hadronic physics because of the contribution it makes to the mass of the proton [7,8]. The matrix element of $\theta_{\mu\nu}$ in the proton is

$$\langle p | \theta_{\mu\nu} | p \rangle = 2p_\mu p_\nu \quad (5)$$

The trace of this equation is

$$\langle p | \theta_\mu^\mu | p \rangle = 2m_p^2 \quad (6)$$

If we were to lose the anomaly, then we would break Poincaré invariance at the point of regularisation and our parton distributions would correspond to a proton with the wrong mass.

To see how the anomaly contributes to the unpolarised structure function we apply the operator product expansion analysis to unpolarised photon gluon fusion at $O(\alpha_s)$ — Fig. 1. Here $q_\mu = (q_0; 0_T, q_3)$ and $p_\mu = (p_0; 0_T, p_3)$ are the momenta of the hard photon and the soft gluon respectively; k is the momentum of the struck quark or anti-quark. We consider the transverse cross section where the photon and gluon both carry transverse polarisation and follow the discussion of polarised deep inelastic scattering given in the papers of ref.[9]. A finite quark mass m and gluon virtuality $-p^2$ is used to

The cross section for this photon gluon fusion process is:

$$\frac{\alpha_s}{2\pi} \int_0^{\frac{1}{4}W^2} \frac{dk_T^2}{\sqrt{1 - \frac{4k_T^2}{W^2}}} \left[(2x^2 - 2x + 1) \left(\frac{x}{Q^2(1-x)} + \frac{1}{k_T^2 + m^2 - p^2x(1-x)} \right) + x(1-x) \frac{2m^2 + p^2(2x^2 - 2x + 1)}{(k_T^2 + m^2 - p^2x(1-x))^2} \right] \quad (7)$$

where W^2 is the centre of mass energy squared. There are three distinct contributions to the total phase space. The first term in equ.(7) receives contributions only from $k_T^2 \sim Q^2$, where the photon makes a local interaction with the target gluon. The second term receives contributions from the full range of k_T^2 . It is sensitive to the mass singularity at zero k_T^2 and gives the $\ln Q^2$ dependence of the total cross section after we integrate over the transverse momentum. The third term is infra-red dominated and receives contributions only from $k_T^2 \sim m^2, -p^2$.

At $O(\alpha_s)$ the cross section for photon gluon fusion is the sum of the gluonic coefficient $C^g(x, \alpha_s)$ and the quark distribution of the gluon $(q + \bar{q})^{(g)}(x, Q^2)$. In the parton model we set the coefficients equal to the “hard” part of the phase space, where “hard” is defined to include the whole phase space which is not subtracted into the target wavefunction via the factorisation theorem. The local γ^* (glue) interaction is clearly “hard” in this picture and is included into the parton model as a part of the gluonic coefficient $C^g(x, \alpha_s)$. The simplest way to isolate the mass singularity involves choosing a cut-off on the transverse momentum of the quarks so that we identify the gluonic coefficient with the phase space corresponding to quark jets with transverse momentum $k_T^2 > \mu_{fact}^2$, where μ_{fact}^2 is some finite scale ($Q^2 \gg \mu_{fact}^2$ and $\mu_{fact}^2 \gg -p^2, m^2$). With this cut-off, the hard parton model coefficient is:

$$C_{PM}^g(x, \frac{Q^2}{\mu_{fact}^2}, \alpha_s) = \frac{\alpha_s}{2\pi} \left[(2x^2 - 2x + 1) \left(-1 + \ln \frac{Q^2}{\mu_{fact}^2} + \ln \frac{1-x}{x} \right) \right] \quad (8)$$

The remaining soft part of the phase space is identified with the quark distribution of the gluon $x(q + \bar{q})_{PM}^{(g)}(x, \mu_{fact}^2)$, which includes all quarks and anti-quarks with transverse momentum less than μ_{fact}^2 :

$$(q + \bar{q})_{PM}^{(g)}(x, \mu_{fact}^2) = \frac{\alpha_s}{2\pi} \left[(2x^2 - 2x + 1) \ln \frac{\mu_{fact}^2}{m^2 - p^2x(1-x)} + x(1-x) \frac{2m^2 + (2x^2 - 2x + 1)p^2}{m^2 - p^2x(1-x)} \right] \quad (9)$$

We now compare this parton model distribution with the renormalised quark distribution, which we calculate via the operator product expansion.

Working in the light cone gauge ($A_+ = 0$), the quark distribution is the renormalised version of the graph in Fig. 2:

$$4p_+^2 x(q + \bar{q})^{(g)}(x) = g^2 \int \frac{d^4k}{(2\pi)^4} \delta(x - \frac{k_+}{p_+}) (2\pi) \delta((k-p)^2 - m^2) \frac{\text{Tr} \left[(\hat{k} + m) \hat{\epsilon}^* (\hat{k} - \hat{p} + m) \hat{\epsilon} (\hat{k} + m) \gamma_+ k_+ \right]}{(k^2 - m^2 - i\epsilon)^2} \quad (10)$$

The k_+ and k_- integrals are carried out using the two delta function constraints to yield an ultra-violet divergent integral in the Euclidean k_T^2 , which needs to be renormalised. We can choose to regularise this ultra-violet divergence via dimensional regularisation or the introduction of a Pauli-Villars term – both of which respect the anomaly. If we use dimensional regularisation, then we continue the physics in the transverse dimensions from $D = 2$ to $D = (2 - 2\epsilon)$ dimensions; the ultra-violet divergence appears as a term proportional to $\frac{1}{\epsilon}$, which is subtracted out as the infinite renormalisation constant of the parton distribution. The sum over the transverse polarisations of the gluon is

Equ.(10) evaluates as

$$4x(p_+)^2 2\alpha_s \int_0^\infty \frac{d^{2-2\epsilon} k_T}{(2\pi^2)^{2-2\epsilon}} \left[\frac{(2x^2 - 2x + 1) + \frac{2\epsilon}{D} 2x(1-x)}{k_T^2 + m^2 - p^2 x(1-x)} + x(1-x) \frac{2m^2 + (2x^2 - 2x + 1)p^2}{[k_T^2 + m^2 - p^2 x(1-x)]^2} \right] \quad (12)$$

in $D = (2 - 2\epsilon)$ dimensions. If no ultraviolet cutoff is imposed, then the integral

$$\int d^{2-2\epsilon} k_T \frac{1}{k_T^2 + m^2 - p^2 x(1-x)} \quad (13)$$

develops an ultra-violet pole $\frac{1}{\epsilon}$, which comes from k_T^2 much greater than the parton model cut-off μ_{fact}^2 . This pole cancels with the ϵ term in the numerator of equ.(12) to yield a finite term which is induced by the regularisation: the (trace) anomaly in the energy-momentum tensor. This anomalous term is independent of how we next make the minimal subtraction to obtain the renormalised parton distribution.

In the $\overline{MS}$ scheme the renormalised quark distribution is

$$(q + \bar{q})_R^{(g)}(x, \mu^2) = (q + \bar{q})_{PM}^{(g)}(x, \mu^2) + C_A^g(x, \alpha_s) \quad (14)$$

where C_A^g is the anomaly at $O(\alpha_s)$

$$C_A^g(x, \alpha_s) = \frac{\alpha_s}{\pi} x(x-1) \quad (15)$$

and μ^2 is the renormalisation scale. Here we have subtracted out the divergent term $\frac{\alpha_s}{2\pi}(2x^2 - 2x + 1)(\frac{1}{\epsilon} - \gamma_E + \ln 4\pi)$ into the renormalisation constant. In the general minimal subtraction scheme we subtract out a divergent term proportional to $(\frac{1}{\epsilon} + a)$, where a is some constant; the renormalised quark distribution is equal to the parton model distribution in equ.(9) with $\mu_{fact}^2 = \mu^2 e^{\ln 4\pi - \gamma_E - a}$ plus the subtraction independent anomaly, which is left behind by the ultra-violet regularisation. Pauli-Villars regularisation yields the same renormalised quark distribution as eqs.(14,15). In this case, the anomaly comes from k_T^2 of order the mass squared of the Pauli-Villars fermion in the second term of equ.(12).

The renormalised quark distribution corresponds to a gluonic coefficient which is different to the parton model by the anomalous term in equ.(15); viz.

$$C_{OPE}^g(x, \frac{Q^2}{\mu_{fact}^2}, \alpha_s) = C_{PM}^g(x, \frac{Q^2}{\mu_{fact}^2}, \alpha_s) - C_A^g(x, \alpha_s) \quad (16)$$

Since the anomaly term $C_A^g(x, \alpha_s)$ is a polynomial in x at $O(\alpha_s)$, it describes a local γ^* (glue) interaction. Some of this local interaction is included as a contact interaction with the target wavefunction within the OPE approach, which offers the most rigorous treatment of the total deep inelastic cross-section. The parton model treatment of the local γ^* (glue) interaction is complete if one can treat the proton target as an ensemble of perturbative quark and gluon degrees of freedom. However, it is not clear ab initio that the parton model “scheme” is sufficiently general that it can describe all local interactions between the hard photon and the background colour mean field in addition to the perturbative glue. In particular, it is not clear that the former interaction has the same two-quark-jet signature that we expect from photon gluon fusion in perturbation theory. The background field via the anomaly is important in determining the mass of the proton, equ.(6). We need to understand how it matches onto the perturbative glue. The factorisation theorem tells us how to treat the infra-red collinear singularities but does not tell us how to treat the local γ^* (glue) interaction, which is strictly non-collinear.

The parton model gluonic coefficient is recovered from the operator product expansion analysis if we define our parton model quark distribution to be

$$x(q + \bar{q})_{PM}(x, Q^2) \equiv x(q + \bar{q})_R(x, Q^2) - x g_R \otimes C_A^g(x, Q^2) \quad (17)$$

Note that this $x(q + \bar{q})_{PM}(x, Q^2)$ is not the same object that we obtain with a fixed ultra-violet cut-off

is the difference of two renormalised quark distributions — each of which includes the effect of the anomaly at infinite momentum.

In the parton literature it is commonly assumed that the parton model distributions can be written as light-cone correlation functions [10,11]

$$\begin{aligned} q(x) &= \frac{1}{2\pi} \int dz_- e^{-ixz_- p_+} \langle p | \bar{q}(z_-) \gamma_+ \mathcal{P} e^{ig \int_0^{z_-} dy_- A_+} q(0) | p \rangle_c \\ \bar{q}(x) &= -\frac{1}{2\pi} \int dz_- e^{ixz_- p_+} \langle p | \bar{q}(z_-) \gamma_+ \mathcal{P} e^{ig \int_0^{z_-} dy_- A_+} q(0) | p \rangle_c. \end{aligned} \quad (18)$$

(The moments of these correlation functions project out the target matrix elements of the operators in the OPE.) It is clear from our discussion that this identification needs to be modified according to equ.(17) because of the anomaly.

The correlation function offers a simple, physical picture of the anomaly in deep inelastic scattering. In a quark model (which has an inherent ultra-violet cut-off) the non-local matrix element in equ.(18) has the interpretation that we take out a quark (insert an anti-quark) in the nucleon and re-insert it (take it out) at position z_- along the light-cone. The $z_- \rightarrow 0$ limit of this matrix element is the same object that appears in Schwinger's derivation of the anomaly, which uses point splitting [12] (along the light-cone). Intuitively, one can think of the anomaly in deep inelastic scattering as a zero correlation length effect which is missing in the parton model.

We now compare our results with the anomaly in polarised deep inelastic scattering. The anomaly contribution to the renormalised, unpolarised quark distribution (equ.(14)) arises in the same way as the axial anomaly contribution to the spin dependent quark distribution [9], which is measured in polarised deep inelastic scattering. The anomaly comes from k_T^2 much greater than the parton model cut-off. Clearly, the theory of polarised and unpolarised deep inelastic scattering should be formulated in a consistent way. If we imposed some ultra-violet cut-off on the k_T^2 then we would lose the trace anomaly in the unpolarised structure function and also the axial anomaly in the polarised structure function. This means that the EMC spin effect [13] and the physics of the unpolarised structure function have to be discussed together as part of the same problem.

The renormalised spin dependent quark and gluon distributions which are measured in polarised deep inelastic scattering are

$$2Ms_+(p_+)^{2n} \int_0^1 dx x^{2n} \Delta q_k(x, Q^2) = \langle p, s | \left[\bar{q}(0) \gamma_+ \gamma_5 (iD_+)^{2n} \frac{\lambda^k}{2} q(0) \right]_{Q^2}^R | p, s \rangle_c \quad (19)$$

$$2Ms_+(p_+)^{2n} \int_0^1 dx x^{2n} \Delta g(x, Q^2) = \langle p, s | \left[\text{Tr } G_{+\alpha}(0) (iD_+)^{2n-1} \tilde{G}_+^\alpha(0) \right]_{Q^2}^R | p, s \rangle_c \quad (n \geq 1) \quad (20)$$

where $\tilde{G}_{\mu\nu} = \frac{1}{2} \epsilon_{\mu\nu\alpha\beta} G^{\alpha\beta}$ is the dual tensor and s_μ denotes the proton spin vector (M is the proton mass). The spin dependent distributions have to be renormalised consistent the axial anomaly, which says that any ultra-violet regularisation that respects gauge invariance does not respect chirality as a good symmetry. The renormalisation of each of the C-even axial tensors in equ.(19) involves a gauge dependent counterterm $k_{\mu\mu_1 \dots \mu_{2n}}$. These $k_{\mu\mu_1 \dots \mu_{2n}}$ define a gauge dependent gluonic distribution $\kappa(x, Q^2)$ [14].

There is an important physics difference between the anomalies in unpolarised and polarised deep inelastic scattering. In the unpolarised case the physical energy-momentum tensor is conserved: the canonical identification of $x(q + \bar{q})_R$ with a quark momentum distribution holds true in the renormalised theory. The physical axial vector current is not conserved [15] and has a two-loop anomalous dimension, which is induced by the anomaly [16] — it does not measure spin [14,17]. This means that $\Delta q_R(x, Q^2)$ does not have a canonical interpretation. The colour mean field in the proton should be manifest explicitly in $\Delta q_R(x, Q^2)$. This effect may be seen as an OZI violation in the spin dependent structure function g_1 at large x [14].

Just as in the unpolarised case (equ.16)), the renormalised quark distribution in equ.(19) yields a spin dependent gluonic coefficient which differs from the parton model. The parton model coefficient

where $\tilde{C}_A^g$ is the anomalous coefficient at $O(\alpha_s)$. It is important to distinguish the $\Delta g_R(x, Q^2)$ in equ.(21) from the gauge dependent $\kappa_R(x, Q^2)$. In the light-cone gauge $A_+ = 0$ (where the parton model is usually formulated) one finds $\kappa_R(x, Q^2) = \Delta g_R \otimes \tilde{C}_A^g(x, Q^2)$. However, in a covariant gauge $\kappa_R(x, Q^2)$ is not invariant under gauge transformations — in contrast to the physical $\Delta q_R(x, Q^2)$ and $\Delta g_R(x, Q^2)$ [14]. In polarised deep inelastic scattering the axial anomaly introduces a second set of (gauge dependent) gluonic operators. In unpolarised deep inelastic scattering the trace anomaly involves the same leading twist operators that define the regular gluon distribution in equ.(3) in order to yield the trace in equ.(4) — see also [5].

In summary, the anomaly means that the local γ^* (glue) interaction is treated differently in the operator product expansion and parton model treatments of both unpolarised and polarised deep inelastic scattering. Since an operator analysis of anything other than the total deep inelastic cross-section is intractable, there is no clear way of renormalising the initial and final state wavefunction in other high-energy collisions. It is interesting to consider the possibility that the anomaly might induce a process dependence in the parton distributions at greater than or equal to next-to-leading order in α_s .
